Abstract: The pKₐ values of water and the hydrogen ion (proton) in water are 14 and 0, respectively. Yet, many textbooks of general, organic, and, to a lesser extent, inorganic chemistry provide the incorrect values 15.74 and -1.74, respectively. This column briefly introduces the long-standing issue of these two different pairs of values, the consequences it bears when teaching general chemistry, and expresses the hope that it may be solved soon.

**Keywords**: Acid-base equilibria · Activity · General chemistry · pKₐ of H₃O⁺ · pK₈ of water · Thermodynamics

A sense of incredulity and astonishment pervades the audience of ca. 250 students when I present the data in Table 1 in my General Chemistry I (Inorganic Chemistry) course. This happens usually during the third week of the first semester in the curriculum for the students of chemistry, chemical engineering, biochemistry, and interdisciplinary sciences at ETH Zürich. There are two equilibrium constants concerning the acid-base behaviour of such a fundamental compound as water, and two different pairs of values for pKₐ(H₂O) and pK₈(H₃O⁺), depending on which textbook one consults. I consider this to be not only confusing for the students, but also embarrassing for the chemical community as a whole. Let me get it straight from the beginning: the correct values are pKₐ(H₂O) = 14 and pK₈(H₃O⁺) = 0. There are three publications that convincingly show how the correct values can be derived by applying quite simple, yet proper thermodynamic criteria, i.e. most importantly, the correct standard state for water and activities instead of molar concentrations. The first one, published in 1914, is from a group of authors (including myself) who have taught and still partly teach general chemistry at ETH,[1] the second one has been authored by Silverstein and Heller in 2017,[2a] and the third one is a more recent contribution to Librettexts Chemistry by Neils and Schaerter.[3] Thus, the interested reader – including high school teachers – is invited to consult these three articles for details I will no longer present here. Note, however, that the issue at stake has been discussed long before in the literature.[4]

The textbooks in Table 1 represent a random choice of books I happen to have, or had, in my office. However, a more extensive number of textbooks have also been listed by others, according to the specific criterion of the pKₐ values of water.[5] It is important to note that several other general chemistry textbooks do not provide these values at all in their pKₐ tables, possibly out of prudence. It has also been pointed out[2,3] that the incorrect values are mainly to be found in organic chemistry textbooks, as a consequence of an influential 1960 paper by Ballinger and Long in JACS.[4] While this is most likely true, a notable case for inorganic chemistry, at least for books written in German, is the renowned Riedel/Janiak (Table 1, entry 7). On the other hand, the famous March’s Advanced Organic Chemistry features for the first time the correct values in its 8th edition in 2020, though the erroneous values are still given in brackets (entry 4). Finally, the important monograph by Bell (entry 9) listed the incorrect values back in 1959 (and in the 2nd edition of 1973 as well).

In the specific case of my course, taking into account that my students do not yet have a detailed knowledge of thermodynamics to understand a thorough treatment of the problem, how do I go about explaining why the pair of values 15.74 and -1.74 is incorrect? I need to rely on simple chemical arguments and partly even on intuitive ones. The two differences from the correct values amount in absolute terms to 1.74, which corresponds to log 55.5, and 55.5 is the molar concentration of water in water. The fact that the concentration of the solvent in itself should account for significant differences in the magnitude of two equilibrium constants is intuitively somewhat suspicious, isn’t it? However, on a more solid ground, if one formulates an equation for the dissociation of water in water, i.e. for its behaviour as an acid, it is self-evident that the same equation describes the self-ionization of water with an accepted equilibrium constant $K_w = 10^{-14}$ at 25 °C, hence pK₈ = 14 (Scheme 1). Accordingly, since we are dealing here with one and the same reaction/equilibrium, there are no rational reasons to assume two different equilibrium constants under the exact same conditions. After all, even simple thermodynamics is not an opinion!
H₂O + H₂O ⇌ H₃O⁺ + OH⁻

$$K_w = K_w(H_2O) = \frac{a(H_3O^+)}{a(OH^-)} = 1 \cdot 10^{-14}$$

H₃O⁺ + H₂O ⇌ H₄O²⁺ + H₂O

$$K_a(H_3O^+) = \frac{a(H_4O^{2+}) \cdot a(H_2O)}{a(H_3O^+) \cdot a(H_2O)} = 1$$

Scheme 1. The fundamental equilibria for the self-ionization of water, the acid behaviour of H₂O and H₃O⁺, and their correct thermodynamic equilibrium constants, under standard conditions.

Before I come to the second constant, 0 < –1.74 for the pKᵢ value of Hᵢ⁻, and how I explain it to my students, it is important to realize that the hydrated nature of the hydrogen ion H⁺ (proton) in water is more complex than the common representation as H₂O⁺ implies. In fact, it has been shown by Stoyanov, Reed and coworkers[9] that H(H₂O)⁺ is the unique form of H⁺ in aqueous solutions of ionized acids. Thus, the more appropriate notation of the hydrogen ion in water should be H₃O⁺ rather than H₂O⁺, contrary to what is still adopted in many textbooks and taught in high school and in undergraduate courses. Nonetheless, there are many examples in the literature of simple salts of the solvated proton H(H₂O)⁺ that have been isolated in pure form and characterized by X-ray crystallography for n = 1, 2, 3, and 4. Three of them are shown in Fig. 1. The first one, (H₂O)NO₃, hydronium nitrate, has been reported as nitric acid monohydrate, thereby reflecting the stoichiometry of the compound which crystallizes from equimolar mixtures of nitric acid and water at low temperature.[10] Values between –1.3 and –1.5 can be found in the literature for the pKᵢ of nitric acid.[10] This value is higher (less negative) than the purported value of –1.74 for H₃O⁺. The very fact that hydronium nitrate exists as such indicates that water is more basic than the nitrate ion, thereby retaining the proton in the solid state. This makes it very plausible that H₃O⁺ will be a weaker acid than nitric acid in solution as well, meaning that its pKᵢ cannot be –1.74.

Furthermore, the basicity of the hexafluoroantimonate anion in the other two salts in Fig. 1 is extremely low because the conjugate acid HSbF₆⁻ is actually a superacid.[11] Thus, SbF₆⁻ can be viewed as a totally innocent counterion, though it engages in the solid state in hydrogen bonding with H₃O⁺[10] and H₂O⁺ (Zundel ion),[11] respectively. Nonetheless, these two salts are the available pure forms of the monohydrated and dihydrated hydrogen ion, respectively, the latter containing H₂O⁺ and H₃O⁺ in a 1:1 ratio, forming the strongly hydrogen-bonded H₄O⁵⁺ ion. Thus, one can in principle imagine to use either one of these two salts as suited starting materials for the preparation of a corresponding buffer having pH = pKᵢ by applying the Henderson-Hasselbalch equation:

$$\text{pH} = pK_a + \log \left(\frac{[H_2O]}{[H_3O^+]}\right)$$

Caution: What follows is sort of a reductio ad absurdum, or apogogical argument, that pKᵢ (Hᵢ⁻) cannot ever be –1.74. Still, for the advocates of this value, and systematically using molar concentrations instead of activities, such a hypothetical buffer would display a pH = pKᵢ = –1.74 only in the case of equal molar concentrations of 55.5 M for both H₃O⁺ and its conjugate base H₂O. However, such a concentration is only possible for pure water, meaning that this buffer is chemically and physically a non-existent entity, i.e. an absurdity that appears to be quite convincing for the students.

By way of a conclusion, it is comforting that the authoritative Journal of the American Chemical Society has recently taken up the issue in one of its JACS Video Bytes,[12] unmistakably explaining that the correct values at stake are pKᵢ(H₂O) = 14 and pKᵢ(H₃O⁺) = 0. It will be interesting to see how long it takes until the incorrect values are completely eradicated from both textbooks, high school and undergraduate chemistry courses.

[8] For example, the Hollemann / Wiberg (Table 1, entry 3) reports pKᵢ(HNO₃) = –1.44 (p. 833).
